Numerical and Experimental Research on Hydraulically Generated Noise of a Regenerative Automotive Fuel Pump

Ji-Fu Wang, Hui-Hua Feng, Yong-Xuan Huang, and Xiao-Long Mou

Abstract—Regenerative pumps are receiving increasing interest in industry because of their low cost, low-specific speed, compactness and ability to deliver high heads with stable performance. However, the regenerative pump used in automotive is facing a noise problem. To understand the mechanism in detail, Computational Fluid Dynamics (CFD) and Computational Acoustic Analysis (CAA) together were used to understand the fluid and acoustic characteristics of the fuel pump. The fluid dynamic characteristics of the regenerative fuel pump were investigated numerically using three-dimensional steady and unsteady Reynolds-averaged Navier-Stokes analysis with a shear stress transport turbulence model in ANSYS-CFX 15.0. After the CFD model was validated by the mass flow rate from experiment, the pump inner wall pressure fluctuations extracted from the unsteady flow calculation were used to implement acoustic analysis using finite/boundary element method, vibration-acoustic coupling method and Automatically Matched Layer (AML) method in LMS Virtual. Lab Rev12. Comparing the computational and experimental results shows that sound pressure levels at the observer position are consistent at high frequencies, especially at blade passing frequency.

Index Terms—Regenerative pump, pressure fluctuation, dipole, BPF noise.

I. INTRODUCTION

Regenerative pumps have found applications in many industrial areas which require high heads at low flow rates including automotive and aerospace fuel pumping, booster systems, water supply, agricultural industries, shipping and mining, and chemical and food processing systems [1]. The fluid and NVH characteristics of regenerative fuel pump need more attention simultaneously. Both vibrations and noise can affect the regenerative pump performance and its life. In regenerative pumps, the sources of vibrations and noise may lie in hydraulic or mechanical aspects’ but under normal operating condition, the blade passing frequency is the most usual excitation of vibrations and noise. This frequency results from the nonuniformity of the flow at the impeller outlet which is caused by the effects of the rotor-stator interaction. Many researchers have investigated the fluid performance of regenerative pump in theoretical, numerical and experimental methods.

Theoretically and numerically, Badami [2] presented a hypothesis for evaluating the circulatory flow rate and based his theory on considering the centrifugal force field in the side-channel and in the impeller vane grooves. He used momentum exchange theory to predict head-flow curves and compared theoretical and experimental data. Subsequently, Engeda [3] and Song et al. [4] developed a modified theoretical model that can explain the change in the circulatory velocity caused by the variation in channel area. Several loss models were assumed by the authors and the results of predictions were compared with experimental and CFD data. Raheel [5] proposed a mathematical model to predict the performance of Delphi automotive fuel pump. Excellent agreement between theoretical and experimental data was observed at the design point. Yoo et al. [6] presented equations to calculate the geometry of rotating flows. They developed an improved mathematical model to suggest systematic methods to find the circulatory flow rate, mean inlet and outlet radii of the impeller, and slip factor. Quail et al. [7] numerically modeled the flow field of a regenerative pump in a manner that had not been achieved previously. The pump performance was numerically assessed without the need of a linear region factor or other data from the experiments conducted on regenerative pumps by using a physically valid geometry model and by resolving the circulatory velocity in the peripheral direction. Karanth et al. [8] presented an approach of Computational Fluid Dynamics (CFD) for simulating and analyzing the flow field within a regenerative pump and validation study of the CFD results with the experimental work, they concluded that the number of impeller vanes and splitter vane at the exit chamber would contribute significantly in terms of static pressure rise across the pump.

Depending on the experimental investigation, Hübel et al. [9] conducted a visualization of three-dimensional flow by using the laser light sheet technique in combination with digital image processing. They studied the influence of vane angles of \(45\)˚, \(60\)˚ and \(90\)˚ on the performance of regenerative pump. It was also concluded that the vane angle \(45\)˚ has the best efficiency from other studied angles. Choi et al [10] studied the effect of inclined blade angles of \(0\)˚, \(\pm 15\)˚, \(\pm 30\)˚, and \(\pm 45\)˚, and radial chevron impellers with chevron angles of \(15\)˚, \(30\)˚ and \(45\)˚ on the optimization of regenerative pump performance. Among all blade configurations tested in their study, the chevron blade angle of around \(30\)˚ exhibited the highest head with reasonably good efficiency. Mekhail et al. [11] experimentally studied a regenerative blower system with impellers of different inlet blade angles of \(90\)˚, \(115\)˚, \(125\)˚ and \(15\)˚. The experimental results showed that the pressure head and the efficiency depended strongly on the blade inlet and outlet flow angles as well as on the blade geometry, and that the best blower performance could be obtained at an inlet flow angle of \(125\)˚ confirmed by CFD.
simulation analysis. In certain fuel pump module application, Rossetti et al. [12] detected an excessive noise level around the blade passing frequency on test bench, and designed a group of experiments to find the reason, the experimental results showed that the failure was related just to a flow noise. They optimized the noise level through modifying the feed tube. Heo et al. [13] performed a multi-objective optimization to simultaneously enhance the aerodynamic and aeroacoustic performance of a side channel-type regenerative blower. Three arbitrarily selected optimum designs of the regenerative blower increased more significantly in efficiency and decreased in sound pressure level than in a reference design.

Most previous studies focused on the fluid dynamic performance of regenerative turbomachines, few have investigated the noise caused by the flow circulating in the pump. The present work aims to build reasonable models that could simulate the flow and noise performance of a regenerative automotive fuel pump. To achieve this objective, the CFD and CAA models were considered for the regenerative pump. For verifying the simulation results, the fluid and noise performance tests were applied. Accuracy of the simulations was assessed by comparisons to experimental data. This work was intended to lay the foundation for further study on the noise optimization of regenerative fuel pump.

II. REGENERATIVE FUEL PUMP GEOMETRY

The regenerative fuel tank-pump system consists of a fuel tank and a fuel pump module, plotted in Fig. 1. For CFD simulation, we just considered the flow domain in the fuel pump module, as shown in Fig. 2. Simplification was considered in the outlet domain, and the required pressure rise is 400 kPa at a mass flow rate of 20.5 g/s. The regenerative fuel pump is operated at 6000 rpm, and the impeller has 47 blades with chevron blade angle of 30˚. More detailed specifications are shown in Table I, and sectional view of the impeller in Fig. 3.

III. STEADY STATE FLUID DYNAMIC ANALYSIS

For flow analysis in the regenerative fuel pump, this work used ANSYS CFX 15.0. Results were obtained by solving the three-dimensional RANS equations using a finite volume discretization method. The computational domain was obtained through SolidWorks, and ICEM-CFD was used to generate the computational meshes. ANSYS CFX-Pre, Solver, and Post were used to define the boundary conditions, solve the equations, and for post processing, respectively. A high-resolution scheme with second-order accuracy in space was used for the numerical scheme of the convection terms in the governing equations.

This work used the k-ω-based shear stress transport (SST) turbulence model for turbulence closure. The SST model solves a k-ω model in the wall region and a k-ε model in bulk flow. Between these two models a blending function ensures a smooth transition. Bardina et al. [14] showed that the SST model more effectively captures recirculating flow under an adverse pressure gradient than other eddy viscosity models. The near-wall turbulence model used in ANSYS-CFX 15.0 switches between a low-Reynolds number model and an empirical wall function according to the y+ value of the first grid point from the wall. In the present simulations, by adjusting y+ to be less than 2 as shown in Fig. 2, the low-Re version of the SST model, which adapts the low-Re k-ω model developed by Wilcox [15] in the near-wall region, was employed.

The computational domain for the numerical analysis consists of a rotating domain (impeller domain) and two stationary domains (inlet and outlet domains). Gasoline was considered as the working fluid. The total pressure 0 kPa and 400 kPa were assigned at the inlet and outlet domain.
respectively, and the rotating speed, 6000 rpm, was set to the impeller domain. The adiabatic and no-slip conditions were set at the solid surfaces in the computational domain. A frozen rotor method was used at the interface between the stationary and rotating domains in steady state computations.

All meshes in this work were created using the meshing program ICEM (ANSYS Inc.). For establishing grid independency, analysis was carried out with number of elements restricted to approximately 1 million, 2 million and 4 million elements containing hybrid hexahedral/tetrahedral grids, and the grids were refined at the wall region where the flow properties change rapidly. The mass flow rates of the three schemes and experiment are shown in Table II. Since the variation in the mass flow rate values was less than 1.2% for models containing elements greater than 1 million, mesh size of approximately 1 million was adopted to save the computational time, and relative discrepancy between experimental and computational results was 1.9%.

### IV. ACOUSTIC ANALYSIS

#### A. Unsteady State Fluid Dynamic Analysis

Based on the steady RANS analysis, unsteady RANS analysis extracted fluid dynamic sources to analyze the acoustic characteristics of the regenerative fuel pump. In the unsteady computation, a transient rotor stator method was used at the interface between the stationary and rotating domains, the time step and coefficient loops for time scale control were set to $2.12766 \times 10^{-5}$ s and 10 times respectively in order to reduce all maximum residuals to a value below $10^{-5}$. This provided 10 time steps per impeller blade passage. Since the nature of flow is unsteady, it requires numerical analysis until the transient fluctuations of the flow field become time periodic as judged by the pressure fluctuations. In the present analysis this has been achieved after 5 complete rotations of the impeller. The pressure at the monitor points are recorded corresponding to each rotation of the impeller by time step advancement, as shown in Fig. 4 and Fig. 5. The data extracted from the fifth revolution will be used for the following acoustic analysis.

The CFD approach is beneficial in the flow visualization to extend the knowledge of the flow physics. Fig. 6 represents the streamline of the gasoline circulating in the pump, the path lines plot indicates the helical or corkscrew motion that occurs within the pump. This coincides with the observation by Quail et al. [16].

and do not change much until section A5, meaning that the fluid is fully developed during the region. After that, fluid velocities become to decrease, as the pressure is higher at the place near the outlet. It can demonstrate that the physical range of a pump operation is composed of five regions, namely inlet, acceleration, linear, deceleration, and exit region. The phenomena have been illustrated by Wilson [17] and Senoo [18].

B. Acoustic Analysis

In this work, acoustic analysis was implemented using finite/boundary element method, vibration-acoustic coupling method and Automatically Matched Layer (AML) method in LMS Virtual. Lab Rev12. In this process, the pressure fluctuations on the inner wall of the fuel pump extracted from the unsteady flow were used for acoustic analysis.

The mass and momentum conservation equations can be written as follow

$$\frac{\partial \rho}{\partial t} + \frac{\partial (\rho v_i)}{\partial x_i} = 0$$

(1)

$$\frac{\partial}{\partial t} (\rho v_i) + \frac{\partial}{\partial x_j} (\rho v_i v_j) = -\frac{\partial p}{\partial x_j} + \frac{\partial T_{ij}}{\partial x_j}$$

(2)

where $\rho$ is the fluid density, $v$ the velocity, $T_{ij}$ Lighthill stress tensor. Combining these equations finds Lighthill’s analogy [19] as

$$\frac{\partial^2 \rho}{\partial t^2} - c_0^2 \nabla^2 \rho = \frac{\partial^2 T_{ij}}{\partial x_i \partial x_j}$$

(3)

Ffowcs Williams and Hawings [20] extended equation (3) as follow

$$c_0^2 \nabla^2 \rho = \frac{\partial^2 T_{ij}}{\partial x_i \partial x_j} - \frac{\partial}{\partial x_i} \left[ \rho_0 \delta(f) \frac{\partial f}{\partial x_j} \right] + \frac{\partial}{\partial t} \left[ \rho_0 \delta(f) \frac{\partial f}{\partial x_j} \right]$$

(4)

In the right-hand side of equation (4) the three terms represent quadripole, dipole, and monopole sources respectively. For the regenerative fuel pump studied here, dipole source caused by the pressure fluctuations on the inner wall is the main acoustic source.
Fig. 14 represents the whole acoustic domain for the acoustic analysis, which consists of pump boundary, oil pool boundary, air, gasoline and fuel tank domains. A tetrahedral grid system was constructed in the acoustic domain for acoustic analysis with approximately 136061 grid points to satisfy the target element length ($L \leq c/f$, where $c$ and $f$ indicate the speed of sound and maximum frequency value, respectively). An observer point is set to measure the sound pressure, which is 0.2m below the fuel tank, corresponding to the measure position, as shown in Fig. 15.

C. Experimental Validation

For validating the accuracy of the computational model, acoustic experiment of the regenerative fuel pump was implemented in the semi-anechoic room. The fuel pump was tested under installation condition, as shown in Fig. 16. The 40AK type microphone and 26AK type preamplifier together were used to measure the sound pressure, located 0.2m below the fuel tank. The LMS SCADAS III system was used for data acquisition.

Fig. 17 represents the sound pressure levels comparison between computational and experimental results at the monitor point. As we just considered fluid induced noise, the blade passing frequency (BPF= RPMxN/60, where RPM and N represent the rotational speed and blade number, respectively) noise was the interest we had in the fuel pump. Mechanical noise caused by rotor misalignment and electromagnetic noise caused by DC motor commutators were not considered, which related to the basic frequency and harmonic frequencies corresponding to low and medium frequency range. So the simulational results were lower than experimental results under 3000Hz. Between 3000 and 4000 Hz, sound pressure levels were higher in simulation than that in experiment, the probable reason was that some structures such as feed tubes, flange and damping layer were not considered. Similar trend between simulation and experiment was observed after 4000 Hz, especially at the blade passing frequency(BPF) where SPLs were 45.38 dB and 47 dB respectively, with variation about 3.4%. The regenerative fuel pump noise at high frequency, especially at BPF, is the main problem that the factories are facing, and the level exceeds the standard value. So the computational models established are reasonable to depict BPF noise performance of the regenerative fuel pump.

V. CONCLUSION

The numerical analysis using CFD helped understand the complex flow phenomena that exit in a regenerative pump. Three-dimensional steady and unsteady RANS analyses were carried out to investigate the fluid dynamic characteristics of the regenerative fuel pump, and the CFD results of the mass flow rate only had a relative discrepancy of 1.9% compared to experiment. The regenerative fuel pump inner wall pressure fluctuations extracted from the validated CFD model were used to implement the acoustic analysis. To verify the validity of the acoustic model, SPL test was carried out. The calculated sound pressure levels agreed well with experimental results at high frequencies, especially at blade passing frequency only a relative discrepancy of 3.4% existed. The technique and models established in this work could successfully capture the fluid dynamic and acoustic characteristics of the regenerative fuel pump, which would lay the foundation for studying noise optimization of the regenerative fuel pump.
